The energy harvested on the storage component is thus only 2.4% of the energy converted by the system (1 mJ/cycle), as the main part of the converted energy is lost on the parallel resistance of the transducer (low at high frequencies). Hence, harvested energy can be increased by using components that have small losses at high frequencies.

In this design, the TPSI2140-Q1 is used as an isolated switch for discharging the capacitors after the precharge cycle. The switch is placed in series with a high-ohmic resistor to provide a low-power discharge that takes around two minutes to reach a safe voltage level of less than 60V.

This is due to the initial charging current of the input capacitances of the circuit. Failure to manage inrush current can lead to damaged cables, connectors, or fuses. High-voltage systems (100V+) often use precharged circuits to limit inrush current. This process protects the system from damage, extends lifespan, and increases reliability.
