In STATCOM installations for transmission network applications, the most important control mode, similarly to the case of a transmission SVC, is usually power system voltage control.

In order to turn off the thyristor, it is necessary to reduce the main current below the holding-current level. In an AC circuit, the current passes through zero every half cycle so the turn off of the thyristor also is assured every half cycle.

The circuit in Fig. 5.4A is well known for its poor characteristics, the voltage V_{Co} available across capacitor C to turn off K_p being a decreasing function of I . On the other hand, in the circuit of Fig. 5.4B, in which K_p is turn-off controlled, the same forced commutation circuit produces a far better performance.

Phase control is achieved by resistive or resistive--capacitive networks or by triggering pulses derived from such devices as diacs, unijunction transistors, two-transistor trigger circuits, and neon bulbs. In order to turn off the thyristor, it is necessary to reduce the main current below the holding-current level.
